 Importence of Storey Drift Ratio, Ductity and Performance Point Levels on Multi Story Building with and without Infillls

T. Sandeep, Asst. Prof., Anurag Group of Institutions (Autonomous), Telangana, India.

Abstract:
Multistory buildings with open (soft story) ground floor are inherently vulnerable to collapse due to seismic loads, their constructions is still widespread in develop nations. Social and functional need to provide car parking space at ground level far outweights the warning against such buildings from engineering community. In this study, 3D analytical model of multistory buildings have been generating for different buildings models and analyzing using structural analysis tool ‘ETABS’. To study the effect of ground soft, infill, and models with ground soft during earthquake, seismic analysis both linear static, linear dynamic (response spectrum method) as well as nonlinear static (pushover) procedure have to be perform. The analytical model of building includes all important components that influence the mass, strength, stiffness of the structure. The deflections at each story have to be compare by performing equivalent static, response spectrum method as well as pushover have also be perform to determine capacity, demand and performance level of the considering models. Numerical results for the following seismic demands considering the inelastic behavior of the building, ductility coefficients of structure.

1. Introduction

The capacity of structural members to undergo inelastic deformations governs the structural behaviour and damageability of multi-storey buildings during earthquake ground motions. From this point of view, the evaluation and design of buildings should be based on the inelastic deformations demanded by earthquakes, besides the stresses induced by the equivalent static forces as specified in several seismic regulations and codes. Although, the current practice for earthquake-resistant design is mainly governed by the principles of force-based seismic design, there have been significant attempts to incorporate the concepts of deformation-based seismic design and evaluation into the earthquake engineering practice. In general, the study of the inelastic seismic responses of buildings is not only useful to improve the guidelines and code provisions for minimizing the potential damage of buildings, but also important to provide economical design by making use of the reserved strength of the building as it experiences inelastic deformations. Pushover methods are becoming practical tools of analysis and evaluation of buildings considering the performance-based seismic philosophy. Pushover curve represents the lateral capacity of the building by plotting the nonlinear relation between the base shear and roof displacement of the building. The intersection of this pushover curve with the seismic demand curve determined by the design response spectrum represents the deformation state at which the performance of the building is evaluated.

2. Objectives of Study

1. To study the effect of infill walls and without infill walls on structure.
2. To study of natural frequency of the structure.
3. To study the performance level of the structure.

3. Different Methods of Seismic Evaluation Studies

3.1 Linear Static Analysis

In linear static procedures the building is modeled as an equivalent single-degree of freedom (SDOF) system with a linear static stiffness and an equivalent viscous damping. The seismic input is modeled by an equivalent lateral force with the objective to produce the same stresses and strains as the earthquake it represents. Based on an estimate of the first fundamental frequency of the building using empirical relationships or Rayleigh’s method.

3.2 Linear Dynamic Analysis
In a linear dynamic procedure the building is modelled as a multi-degree-of-freedom (MDOF) system with a linear elastic stiffness matrix and an equivalent viscous damping matrix. The seismic input is modelled using either modal spectral analysis or time history analysis. Modal spectral analysis assumes that the dynamic response of a building can be found by considering the independent response of each natural mode of vibration using linear elastic response spectra. Only the modes contributing considerably to the response need to be considered. The modal responses are compared using schemes such as the square-root-sum-of-squares (SRSS). Time-history analysis involves a time step-by-step evaluation of building response, using recorded or synthetic earthquake records as a base motion input. In both cases the corresponding internal forces and displacements are determined using again linear elastic analyses.

3.3 NONLINEAR STATIC ANALYSIS

Pushover Analysis is a nonlinear static method of analysis. This analysis technique, also known as sequential yield analysis or simply “Pushover” analysis has gained significant popularity during past few years. It is one of the three analysis techniques recommended by FEMA 273/274 and a main component of Capacity Spectrum Analysis method (ATC-40).

Pushover analysis provide information on many response characteristics that cannot be obtained from an elastic static or elastic dynamic analysis. These are [30]:

- Estimates of inter story drifts and its distribution along the height.
- Determination of force demands on brittle members, such as axial force demands on columns, moment demands on beam-column connections.
- Determination of deformation demands for ductile members.
- Identification of location of weak points in the structure (or potential failure modes).
- Consequences of strength deterioration of individual members on the behaviour of structural system.
- Identification of strength discontinuities in plan or elevation that will lead to changes in dynamic characteristics in the inelastic range.
- Verification of the completeness and adequacy of load path.

3.4 NON-LINEAR DYNAMIC ANALYSIS

In nonlinear dynamic procedure the building model is similar to the one used in non-linear static procedures incorporating directly the inelastic material response using in general finite elements. The main difference is that seismic input is modelled using a time history analysis, which involves time-step-by-time-step evaluation of the building response.

3.5 ADVANTAGES OF INELASTIC PROCEDURE OVER ELASTIC PROCEDURES.

Although an elastic analysis gives a good understanding of the elastic capacity of structures and indicates where first yielding will occur, it cannot predict failure mechanisms and account for redistribution of forces during progressive yielding. Inelastic analyses procedures help demonstrate how buildings really work by identifying modes of failure and the potential for progressive collapse. The use of inelastic procedures for design and evaluation is an attempt to help engineers better understand how structures will behave when subjected to major earthquakes, where it is assumed that the elastic capacity of the structure will be exceeded. This resolves some of the uncertainties associated with code and elastic procedures.

4. Analysis of MULTISTORIED BUILDINGS WITH GROUND SOFT STORY AND WITH INFILLS

4.1 DESCRIPTION OF THE SAMPLE BUILDING

The plan layout for all the building models are shown in figures

SYMmetric BUILDing MODELS:
Model 1: Twelve storeyed Building with full infill masonry wall (230 mm thick) in all storeys.

Model 2: Twelve storeyed Building (ground soft story) no walls in the first storey and full brick infill masonry walls (230 mm thick) in the upper storeys.

Model 3: Nine storeyed Building with full infill masonry wall (230 mm thick) in all storeys.

Model 4: Nine storeyed Building (ground soft story) no walls in the first storey and full brick infill masonry walls (230 mm thick) in the upper storeys.
4.2 Design Data:

Material Properties:
Young’s modulus of (M25) concrete, \( E \) = 25.000x10^6 kN/m²
Young’s modulus of (M20) concrete, \( E \) = 22.360x10^6 kN/m²
Density of Reinforced Concrete = 25 kN/m³
Modulus of elasticity of brick masonry = 3500x10³kN/m²
Density of brick masonry = 19.2 kN/m³
Assumed Dead load intensities
Floor finishes = 1.5kN/m²
Live load = 4 kN/m²

Member properties
Thickness of Slab = 0.125m
Column size for twelve storeyed = (0.6m x 0.6m)
Column size for nine storeyed = (0.45m x 0.6m)
Beam size of twelve storeyed = (0.375m x 0.6m)
Beam size of nine storeyed = (0.375m x 0.6m)
Thickness of wall = 0.230m
Thickness of shear wall = 0.30m
Earthquake Live Load on Slab as per clause 7.3.1 and 7.3.2 of IS 1893 (Part-I)- 2002 is calculated as:
Roof (clause 7.3.2) = 0
Floor (clause 7.3.1) = 0.5x4=2 kN/m²

IS: 1893-2002 Equivalent Static method
Design Spectrum
Zone – V
Zone factor, Z (Table 2) – 0.36
Importance factor, I (Table 6) – 1.5
Response reduction factor, R (Table 7) – 5.00

Vertical Distribution of Lateral Load, \( f_i = V_B \frac{w_i h_i^2}{\sum w_i h_i^2} \)

IS: 1893-2002 Response Spectrum Method: Spectrum is applied from fig.2 of the code corresponding to medium soil sites. The spectrum is applied in the longitudinal and transverse directions.

4.3 Manual Calculation
Natural periods and average response acceleration coefficients:

For twelve-storeyed frame building:
Fundamental Natural period, longitudinal and transverse direction, \( T_a = 0.075 \times 36^{0.75} = 1.102 \text{ sec} \)
For medium soil sites, \( S_a/g = 1.36/T = 1.36/1.102 = 1.234 \)

For twelve-storeyed brick infills buildings:
Fundamental natural period longitudinal direction, \( T_a = \frac{0.09 \times 36}{\sqrt{25}} = 0.66 \text{ sec} \)
For medium soil sites, \( S_a/g = 1.36/0.66 = 2.060 \)
Fundamental Natural period, transverse direction, \( T_a = \frac{0.09 \times 32}{\sqrt{20}} = 0.643 \text{ sec} \)
For medium soil sites, \( S_a/g = 1.36/0.643 = 2.11 \)

Design horizontal seismic coefficient, \( A_h = \frac{Z \times I \times S_a}{2 \times R \times g} \)

\( A_h = (0.36/2) \times (1.5/5) \times 2.060 = 0.1124 \) in longitudinal direction.
\( A_h = (0.36/2) \times (1.5/5) \times 2.11 = 0.1139 \) in transverse direction.

5. STOREY DRIFTS

The permissible inter storey drift is limited to 0.004 times the storey height, so that minimum damage would take place during earthquake and pose less psychological fear in the minds of people. The storey drifts of different models along longitudinal and transverse directions are shown in Tables 5.1 to 5.4

Fig 5.11 drift of linear non static analysis of 9th storey buildings in x – direction.

Fig 5.12 drift of linear non static analysis of 9th storey buildings in y – direction.

From the above tables it can be seen that, all storey drifts are within the permissible limit (0.004*h=12mm) except the model-2 and model-4. In model-2 and model-4, the drifts are more than the permissible limit due to soft storeys, this is due to the less stiffness of the structure (because infill walls are not present in the lower storeys) therefore larger drifts are at lower storey than that in above storey because of the stiffness irregularity.

The displacement profiles of the various models for the three different analysis performed in this study are shown in figures 5.1 to 5.12. In these graphs, the abrupt changes in the bottom soft storey of model-2 and model-4 indicate the stiffness irregularity. Hence the inter-storey drift demand is largest in the first storey of model-2 and model-4. In transverse direction also models with full infill shows good results as compared with bottom soft storey model-2 and model-4.

5.2 DUCTILITY RATIO (μ) AND RESPONSE REDUCTION FACTOR (R):

Ductility is another factor that can affect the performance of a building during an earthquake. Ductility is the property of certain materials to fail only after large stresses and strains have occurred. Brittle materials, such as non-reinforced concrete, fail suddenly with minimum tensile stresses, so plain concrete beams are no longer used. Other materials, primarily steel, bend or deform before they fail. We can rely on ductile materials to absorb energy and prevent collapse when earthquake forces overwhelm a building. In fact, adding steel rods to concrete can reinforce it and give the concrete considerable ductility and strength. Concrete reinforced with steel will help prevent it from failing during an earthquake.

<td>25.8</td>
</tr>
<tr>
<td>Ultimate displacement</td>
<td>456</td>
<td>250</td>
<td>88.2</td>
<td>121</td>
</tr>
</tbody>
</table>
The property which enables structure to withstand severe earthquake is ductility. By enhancing ductility in structure the design seismic forces can be reduced, and more economical structure can be obtained. Reinforced concrete structures have less ductility capacity as compared to steel structures. The ductility ratio and response reduction factor for different building models in longitudinal and transverse direction are shown in tables-5.5 and 5.6.

From the above tables it can be seen that, response reduction factor and ductility ratio decreases as the stiffness of brick wall decreases in bottom storey in model-2 and model-4 along longitudinal and transverse direction.

5.3 PERFORMANCE POINT

The performance point of the building models in longitudinal and transverse directions are shown in figure 5.25 to 5.32 as obtained from ETABS. The values of seismic coefficients $C_A$ and $C_V$ for zone-V are taken from the table 5.11.

6. SUMMARY AND CONCLUSION

The present work attempts to study the seismic response and performance level of different RC buildings located in seismic zone-V. In this study all important components of the building that influence the mass, strength, stiffness and deformability of the structure are included in the analytical model. To study the effect of infill and soft storey building models. The deflections at different storey levels and storey drifts are compared by performing response spectrum method as well as pushover method of analysis.

It is essential to consider the effect of masonry infill for the seismic evaluation of movement resisting RC frames especially for the prediction of its ultimate state. Infills increase the lateral resistance and initial stiffness of the frames they appear to have a significant effect on the reduction of the global lateral displacement.

Infills having no irregularity in elevation having beneficial effects on buildings. In infilled frames with irregularities, such as ground soft storey, damage was found to concentrate in the level where the discontinuity occurs.
